

## Dosimetric Impact of Ac-227 in Accelerator-Produced Ac-225

Actinium-225 ( $^{225}\text{Ac}$ ) has a 10-day half-life and a decay scheme that yields four alpha-particle emissions. This radionuclide is produced by a generator system from the decay of thorium-229. Accelerator-produced  $^{225}\text{Ac}$  via thorium-232 irradiation (denoted  $^{225}/^{232}\text{Ac}$ ) contains a low percentage (0.1-0.3%)  $^{227}\text{Ac}$ ; (21.77 year half-life) at end of bombardment. The biological consequences of this contamination have been recently examined [1]. We examine the contribution of  $^{227}\text{Ac}$  and its daughters to tissue absorbed doses when the level of contamination is 0.7% (by radioactivity) at time of injection. The dosimetric analysis was performed for antibody-conjugated  $^{225}/^{232}\text{Ac}$  administered intravenously to treat patients with hematological cancers.

Published pharmacokinetic models are used to obtain the distribution of  $^{225}/^{232}\text{Ac}$ -labeled antibody and also the distribution of either free or antibody-conjugated  $^{227}\text{Th}$ . Since  $^{227}\text{Th}$  is obtained from the beta decay branch (99% yield) of  $^{227}\text{Ac}$  rather than a more energetically disruptive alpha-emitter decay, it is possible that a significant fraction of the  $^{227}\text{Th}$  generated remains antibody-conjugated. A pharmacokinetic model representing the distribution of radiolabeled antibody in patients with hematologically distributed cancer is adapted from reference [2] to obtain the pharmacokinetics for  $^{225}/^{232}\text{Ac}$  and  $^{227}\text{Th}$ -labeled-antibody. A model representing the pharmacokinetics of free  $^{227}\text{Th}$  is used to model the distribution of unconjugated  $^{227}\text{Th}$  [3]. Under both circumstances,  $^{223}\text{Ra}$  generated by  $^{227}\text{Th}$  decay is simulated using a pharmacokinetic model that is relevant to free  $^{223}\text{Ra}$  [4]. The 1% of  $^{227}\text{Ac}$  that decays to francium-223 ( $^{223}\text{Fr}$ ,  $T_{1/2} = 22$  min) is considered to have a negligible impact on tissue absorbed dose relative to that from  $^{227}\text{Th}$  which is already expected to be very low because of the low initial amount of  $^{227}\text{Ac}$  in  $^{225}/^{232}\text{Ac}$ . The tissue absorbed dose from  $^{227}\text{Ac}$  is negligible in the context of therapy; less than 1.4 mGy/MBq for the top 5 highest absorbed tissues and < 0.007 mGy/MBq for all other tissues. Compared to that from  $^{225}\text{Ac}$ , the absorbed dose from  $^{227}\text{Ac}$  makes up a very small component (<0.4%) of the total absorbed dose delivered to the 5 highest dose tissues: red (active) marrow, spleen, endosteal cells, liver and kidneys when accelerator produced  $^{225}/^{232}\text{Ac}$ -conjugated anti-CD33 antibody would be used to treat leukemia patients. For all tissues, the dominant contributor to the absorbed dose arising from the  $^{227}\text{Ac}$  is  $^{227}\text{Th}$ , the first daughter of  $^{227}\text{Ac}$  which has the potential to deliver absorbed dose both while it is antibody-bound and while it is free. The results suggest that the dose arising from  $^{227}\text{Ac}$  to normal organs is negligible for  $^{225}/^{232}\text{Ac}$ -labeled antibody that targets hematological cancer.
